(57) **ABSTRACT**

Systems and methods for inspecting an object with a scanned beam of penetrating radiation. Scattered radiation from the beam is detected, in either a backward or forward direction. Characteristic values of the scattered radiation are compared to expected reference values to characterize the object. Additionally, penetrating radiation transmitted through the inspected object may be combined with scatter information. In certain embodiments, the inspected field of view is less than 0.1 steradians, and the detector is separate from the source of penetrating radiation and is disposed, with respect to the object, such as to subtend greater than 0.5 steradians in the field of view of the object.

X-RAY INSPECTION BASED ON SCATTER DETECTION

The present application is a divisional application of U.S. Ser. No. 12/368,736, a continuation-in-part application of U.S. Ser. No. 11/608,957, filed Dec. 11, 2006, now issued as U.S. Pat. No. 7,505,556, itself a continuation-in-part application of U.S. Ser. No. 11/238,719, filed Sep. 29, 2005, now issued as U.S. Pat. No. 7,218,704, which is a continuation application of U.S. Ser. No. 10/442,687, filed May 21, 2003, now issued as U.S. Pat. No. 7,099,434, which was a continuation-in-part of U.S. Ser. No. 10/330,000, filed Dec. 26, 2002, and claimed priority from U.S. Provisional Application Ser. No. 60/424,357, filed Nov. 6, 2002, as does the present application. All of the foregoing applications are incorporated herein by reference.

U.S. Ser. No. 12/368,736, of which the present application is a divisional, is also a continuation-in-part of U.S. Ser. No. 11/551,991, filed Oct. 23, 2006, and issued as U.S. Pat. No. 7,551,715, and claims priority, through that application, to US Provisional Patent Applications, Ser. No. 60/729,528, filed Oct. 24, 2005, Ser. No. 60/729,548, filed Oct. 24, 2005, and Ser. No. 60/748,909, filed Dec. 9, 2005. All of the foregoing applications are incorporated herein by reference.

TECHNICAL FIELD

The invention generally relates to inspection systems based upon remote detection of penetrating radiation scattered by an inspected object.

BACKGROUND OF THE INVENTION

X-rays are currently employed for the inspection of cargo containers, including motor vehicles, freight pallets, etc. Current technology, however, typically requires that some structure associated with the inspection system be disposed on either side of the inspected object. Thus, for example, a source of x-rays may be disposed distally with respect to the inspected object while a detection system disposed proximally to the inspected object characterizes the x-rays which have traversed the inspected object. In other modes of x-ray inspection, described in U.S. Pat. No. 6,292,533, issued Sep. 18, 2001 and incorporated herein by reference, a source of penetrating radiation is mounted on a moveable bed which is driven by a stationary cargo container, while a boom extends either a detector or a beam stop to the distal side of the cargo container. Current technology, in summary, requires that the inspected objects or persons either be moved through an inspection system or interposed between a proximal examining component and a distal examining component, one including a source and the other including a detector.

An effective means, however, is desirable for non-intrusively examining personnel as well as the interior of vehicles, cargo containers, or other objects. In particular, with respect to cargo enclosures, it is desirable to detect the presence of people, potential contraband, threats, or other items of interest, without imposing the requirements and constraints of current systems. Combining such an examination with passive sensing of radioactive or fissile material would also be advantageous.

The resolution of information obtained about the interrogated object or person is dependent upon a variety of factors including the distance between the inspection system and the object, and the magnitude and energy spectrum of the x-ray flux. In current systems, as the distance between the X-ray system and the object increases or as the flux decreases, the

image resolution and quality (as manifest in the signal-to-noise, for example) decreases. The decrease in quality is substantially caused by the reduction of backscattered flux captured by the detectors. Current backscatter x-ray imaging systems locate detectors adjacent to the x-ray source, allowing the combined system of source and detectors to be as close as possible to the object being inspected. The proximity of the system to the object creates a high quality image without the need for a high x-ray flux.

However, there are many applications, especially security and surveillance applications, where a larger distance between the imaging system and the object to be inspected would be desirable. One such application is where personnel to be inspected might be carrying explosive devices carried under clothing or concealed in backpacks or bags and the risk of suicide detonation is present. Suicide bombings have often entailed large quantities of metal shrapnel packed around the explosive to maximize the lethality of the device, typically nuts, nails, or ball-bearings.

Current x-ray inspection systems are often inadequate in such applications and are rarely used in applications requiring distances greater than five feet. Current systems can counteract the decrease in image quality by increasing the size of the detectors or using higher flux x-ray sources. However, if the distances are too great, the detectors required will be impractically large. Additionally, as the flux increases, so will the objects exposure, which poses a problem when the object is, or may contain, a person.

One scenario for backscatter inspection from a mobile inspection vehicle is described in U.S. Pat. No. 7,099,434, to Adams et al., issued Aug. 29, 2006 and incorporated herein by reference. Embodiments of that invention can be highly effective at detecting large quantities of explosives or other organic materials in vehicles or other containers. One consideration, however, is that metal objects (such as artillery shells) within a metallic container (such as a vehicle) may not be well-detected unless favorably silhouetted against a brightly scattering background of organic material.

Another issue for backscatter technology is that it can sometimes be difficult to image organic materials when they are placed within or behind significant amounts of high-Z material, such as steel. An example of this might be a small quantity of explosive concealed in the trunk of a vehicle. Because the backscattered x-rays are typically detected in the backward direction (scatter angles typically in the range $140^\circ < \theta < 180^\circ$), the average energy of the scattered x-rays is quite low (about 68 keV for a primary x-ray beam from a 225 kV x-ray source). These low-energy x-rays are then greatly attenuated by the steel body of the vehicle, resulting in a greatly reduced number of scattered x-rays being detected in the backscatter detectors. This problem is often exacerbated because the scattered x-rays reach backscatter detectors having passed through an intervening steel surface at an oblique angle, resulting in an effective thickness of steel that is greater than the actual gauge of the steel.

SUMMARY OF CERTAIN EMBODIMENTS OF THE INVENTION

Representative embodiments of the present invention include a system and a method for inspecting an object. The object is illuminated with a collimated beam of penetrating radiation. Backscattered radiation from the beam is detected. Characteristic values of the backscattered radiation are compared to expected reference values. Based on the comparing, a descriptive category is determined which characterizes the object.

In further embodiments, the penetrating radiation may be x-ray radiation. The descriptive category may, for example, indicate abnormally high metallic content when the characteristic values are less than the expected reference values, or abnormally high organic content when the characteristic values are greater than the expected reference values. The descriptive category may indicate a potential or confirmed security threat according to pre-established security threat criteria.

In some embodiments, the method may further include selecting the object for illumination. This may be based, for example, on optical or non-optical surveillance of an area of interest. The method may also include determining the expected reference values based on illuminating a reference object with the penetrating radiation.

Embodiments of the present invention also include systems and devices adapted to employ any of the foregoing methods.

Embodiments also include an improved inspection system of the type using an enclosure in which are concealed a source of penetrating radiation having a beam that is scannable along at least a first plane and a detector that is responsive to back scattered energy of the beam from an object being inspected. The improvement includes a ramp module housing (i) a horizontal portion of a transmission detector module for detecting radiation energy that has been transmitted through the object being inspected and (ii) at least one forward scatter detector for detecting radiation energy that has been scattered in a forward direction by the object being inspected, such module being physically separated from the enclosure and deployable on a road.

In any of the above, the enclosure may form the outside of a vehicle capable of highway travel. Or the enclosure may be a ruggedized shipping container.

In accordance with other preferred embodiments of the present invention, an inspection system is provided for inspecting an object, the inspection system having a source of penetrating radiation disposed and configured such that the inspected field of view is less than 0.1 steradians (sr). A spatial modulator forms the penetrating radiation into a beam for irradiating the object being inspected. A detector is provided, separate from the source of penetrating radiation, disposed, with respect to the object, such as to subtend greater than 0.5 sr in the field of view of the object.

In accordance with one embodiment of the present invention, the source of penetrating radiation may be placed at the center of a room and a number of portable detectors placed near the walls of the room. Alternatively, the source of penetrating radiation may be placed in an adjacent room and the detectors built into the walls of the room or located in adjacent rooms.

In accordance with further embodiments of the present invention, the source of penetrating radiation, the detector, or both may be located on one or more vehicles, including robotic drone vehicles, capable of road travel. The source of penetrating radiation may be mounted on a swivel mount to allow the beam to be directed at objects in various locations. The inspection system may further include a stabilization system to minimize bounce when the vehicle is traversing rough terrain.

In yet further embodiments of the present invention, the detectors may be located in the ground or ceiling of a passageway and may be camouflaged. Detectors located in the ground may further include structural supports to prevent damage to the detector when objects pass over, and pressure sensors to detect the presence of an object.

BRIEF DESCRIPTION OF THE DRAWINGS

The foregoing features of the invention will be more readily understood by reference to the following detailed description taken with the accompanying drawings:

FIG. 1 is a perspective view, cutaway in part, of a mobile cargo inspection system deployed on a truck capable of on-road travel and scanning of an enclosure such as a vehicle or cargo container while one or both of the inspection system and enclosure are in motion, in accordance with preferred embodiments of the present invention;

FIG. 2 is an image of various vehicles as imaged in backscatter radiation by the system of FIG. 1 in accordance with an embodiment of the invention;

FIG. 3 is a schematic representation of an inspection vehicle, in accordance with embodiments of the present invention, providing inspection capability to either side of the vehicle;

FIG. 4 is schematic representation of an embodiment of the invention in which a source of penetrating radiation and detection modules are concealed within a container;

FIG. 5 shows a modular configuration of an inspection system in which distinct functional components of the inspection system are disposed within coupled modules;

FIG. 6 is a side view of an inspection system deployed from within a self-contained trailer;

FIG. 7 is a rear view of the trailer-borne inspection system of FIG. 6; and

FIG. 8 shows a transmission detector placed at the far side of a vehicle being imaged according to one embodiment of the present invention.

FIG. 9 shows a forward scatter detector placed underneath a vehicle for imaging according to one embodiment of the present invention.

FIG. 10 shows incorporation of a horizontal section of a transmission detector and forward scatter detectors into a rapidly deployable "speed-bump" according to one embodiment of the present invention.

FIG. 11 shows various functional components according to a "Z-Radar"™ embodiment of the present invention.

FIGS. 12A and 12B show aspects of various signal calibration schemes as used in specific embodiments.

FIG. 13 shows details of an embodiment in which several interrogation points are rapidly established.

FIG. 14 shows an inspection system designed to inspect personnel.

FIG. 15 shows an inspection system designed to inspect walls of a building for foreign objects.

FIG. 16 shows an inspection system designed to locate people in an adjacent room with detectors built into the walls of the room.

FIG. 17 shows an inspection system designed to locate people in an adjacent room with detectors located in rooms adjacent to the room of interest.

FIG. 18 shows an inspection system designed to extend the range of existing inspection systems by relocating detectors closer to the object being inspected.

FIG. 19 shows an inspection system with the source of penetrating radiation and detectors located on vehicles capable of road travel.

FIG. 20 shows an inspection system designed to inspect possible IEDs with the detector located on a forward deployed robot.

FIG. 21 shows a top view of an inspection system with the source of penetrating radiation mounted to a swivel mount on a vehicle capable of road travel and the detector mounted on a drone vehicle.

FIG. 22 shows a side view of an inspection system with the source of penetrating radiation mounted to a swivel mount on a vehicle capable of road travel and the detector mounted on a drone vehicle.

FIG. 23 shows an inspection system for inspecting suspect travelers with the x-ray source mounted in the ceiling.

FIG. 24 shows an inspection system for inspecting passing cars with the detectors located along the roadway and the x-ray source mounted above the roadway.

FIG. 25 shows a top view of the detector located in the ground with structural support.

FIG. 26 shows a side view of the detector located in the ground with structural supports and camouflage layer.

FIG. 27 shows a side view of an inspection system with an array of detectors, located in the ground, surrounding the x-ray source.

FIG. 28 shows a top view of an inspection system with an array of detectors, located in the ground, surrounding the x-ray source.

FIG. 29 shows a top view of an inspection system where the detectors are free standing monoliths.

FIG. 30 shows an inspection system in which the signals from detectors at different distances are separated.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

X-ray scattering may be employed for inspection of personnel, vehicles, cargo, or other objects of interest. The term "object" is used inclusively herein to encompass any of the above. In systems employing x-ray scattering, x-rays are formed into a beam that is directed towards the object of interest. When the beam hits the object, scattered X-rays are captured by x-ray detectors and various characteristics of the scattering object may be ascertained, either globally, or with respect to a pixelated image of the object.

As used in this description and in the appended claims, a "cargo container" is a receptacle for the storage or transportation of goods, and includes freight pallets as well as vehicles, whether motorized or drawn, such as automobiles, the cab and trailer of a truck, railroad cars or ship-borne containers. The term "cargo container," as used herein, further includes the structures and components of the receptacle.

The invention described herein serves to characterize materials which may be contained within a cargo container and thus not readily susceptible to visual scrutiny, or, alternatively, may be carried on the person of a human or on another animate subject. The characteristics of a material which might be the object of non-invasive inspection and which lend themselves to detection using the device and method taught by the invention include, but are not limited to, electron density, atomic number, mass density, linear dimensions and shape. These characteristics are unveiled by taking advantage of the various physical processes by which penetrating radiation interacts with matter. Penetrating radiation refers to electromagnetic radiation of sufficient energy per photon to penetrate materials of interest to a substantial and useful degree and include x-rays and more energetic forms of radiation. The interaction of such radiation with matter can generally be categorized as either scattering or absorption processes. Both types of process remove x-ray photons from a collimated (i.e., directional) beam; scattering processes do so by deflecting photons into new directions (usually with loss of energy), while absorption processes simply remove photons from the beam.

Description of the rudiments of a mobile inspection system is to be found in U.S. Pat. No. 5,764,683, issued Jun. 9, 1998,

and incorporated herein by reference. As used in this description and in any appended claims, the term "source" is used in a broad sense to encompass the entirety of the apparatus used to generate a beam of penetrating radiation that is used to irradiate the object under inspection. The source is taken to include the generator of penetrating radiation (the "source", in the narrow sense) which may include an x-ray tube or a radio-isotope. It is, furthermore, to be understood that the term "source" as used herein and in any appended claims, and as designated generally by numeral 30 in the drawings, refers to the entirety of the apparatus used to generate beam 24, and may have internal components that include, without limitation, apertures, choppers, collimators, etc.

Scatter imaging in which the x-rays scattered by a material (typically in a generally backward direction) are employed offers several unique inspection capabilities and operational features. Scatter imaging allows images to be obtained even when the imaged object is accessible from only one side. Moreover, since the scatter signal falls off quite rapidly with increasing depth into the object, backscatter images effectively represent a "slice" of the object characteristic of the side nearest to the x-ray source, thereby reducing problems of image clutter that may confound transmission images. The Compton effect, which dominates x-ray scatter in the energy range typically employed in accordance with the present invention, dominates the interaction of x-rays with dense low-atomic-number (low-Z) materials. Narcotic drugs tend to produce the bright signatures in a backscatter image, as do organic explosives, making backscatter imaging a useful imaging modality for bomb or drug detection. Finally, alignment requirements of the x-ray beam with detectors or collimation devices are less exacting than for transmission imaging thereby enabling rapid deployment in a wide range of inspection scenarios.

Flying-spot technology makes possible the acquisition of images using detectors specifically positioned to collect the scattered x-rays. In a typical flying-spot system, a thin "pencil beam" of x-rays is rapidly and repetitively swept through a source-centered, vertically-oriented "fan" of beam paths that are arranged to intercept the object under inspection. At the same time, the object is moved at a constant, slower speed along a path perpendicular to the fan, on a horizontally moving conveyor belt for example. In this way, the pencil beam is made to traverse the object in point-by-point raster fashion, and the entire object is scanned as it passes through the fan plane over a period ranging from a few seconds to a few minutes depending upon the length of the object.

Although the total scan time may be seconds to minutes in duration, the actual exposure time of any part of the scanned object is only the brief time it takes for the pencil beam to sweep across a given pixel. That exposure time is typically in the range of microseconds, depending on the design and the application, and yields an entrance exposure to the scanned object that constitutes a low dose to the object also means that there is little radiation available to scatter into the environment, so the doses to operators and other bystanders is correspondingly low.

Referring now to FIG. 1, various embodiments of this invention make use of systems in which detectors are mounted on a mobile platform 710, or conveyance, typically capable of road travel, that traverses a large object to be inspected such as a vehicle or a cargo container 712. Conveyance 710 is characterized by an enclosure 714, here, the skin of a van, shown, in cutaway view, to enable depiction of other components of an inspection system. The conveyance can have many alternate embodiments, including but not limited to gasoline, diesel, electric, propane, battery, fuel-cell, or

hydrogen-powered motor vehicles (including vans, trucks, or similar), tracked vehicles, sleds, trailers, cranes, or other equipment that can be put into motion, preferably self-propelled, but also including vehicles tethered and pulled such as under electric power.

Contained within enclosure **714** of conveyance **710** is a source **730** including x-ray tube **732** (shown in FIG. **3**) and chopper **734**. In accordance with preferred embodiments of the invention, source energies are typically below 250 keV, thus the chopper **734** may be smaller than employed in current systems in which higher-energy x-rays are employed. Chopper **734** may be a rotating perforated hub, or a wheel with transmitting spokes, or any number of means, known in the art, for generation of flying spot beams that lie, typically, in a plane approximately orthogonal to the direction of motion **720**. The x-ray tube **732** depicted in FIG. **3**, by way of example, is a panoramic-style x-ray tube that is capable of wide-angle beam generation and additionally may be rotatable to allow scanning on either side of conveyance **710**. Rotating hoop **734**, with apertures **736** and **738**, emits a pencil beam **724**, thereby enabling inspection of objects, possibly on either side of the conveyance, herein referred to as "bilateral" inspection. However, all sources are encompassed within the scope of the present invention when employed in the manner described in the present description. The x-ray source and detectors may be oriented to permit scanning from the conveyance's "driver's side", "passenger's side", or both sides simultaneously.

Various means are known in the art for mechanically or electronically sweeping a beam of penetrating radiation, including, for example, the rotating chopper wheel **734** depicted in FIG. **3** or electronic scanning is described in detail, for example, in U.S. Pat. No. 6,421,420, issued Jul. 16, 2002, which is incorporated herein by reference. In embodiments employing a mechanical rotating chopper wheel **734**, as the chopper wheel rotates in the direction of arrow **722**, penetrating radiation **724** emitted from the target of x-ray tube **732** passes successively through a plurality (typically, three or four) of channels. Wheel **734** is fabricated from a material, typically lead, that blocks transmission of x-rays except through apertures **736**, **738**. X-rays **724** emerge from the currently illuminated channel as a pencil beam that is swept across object **712** undergoing inspection as wheel **734** rotates. The dimensions of the beam **724** typically govern the resolution of a system such as the one depicted. Aperture **736** may have various shapes, and may be circular or rectangular, and may be more specifically tailored. Other x-ray generation approaches may be used to produce a similar sweeping pencil beam, such as spinning discs with elongated slits, wheels with hollow spokes, are alternate embodiments.

Detector modules **100** are carried by conveyance **710** and typically enclosed within enclosing body **714** and concealed from view from outside the conveyance. They may also be carried outside the conveyance for particular applications within the scope of the present invention. Detector modules contain detectors for detecting penetrating radiation from source **730** that has interacted with, and scattered from, contents of the inspected object **712**.

The source of scattering may be characterized as anomalous for the nature of the person or item being scanned. Thus, a person **50** (shown in FIG. **2**) carrying explosives may be detected on the basis of locally enhanced x-ray scatter. A specified characteristic of the scatter, such as a localization or particular disposition with respect to the inspected object, may be ascertained in order to determine threat levels of the object.

Detector modules **100** may also be sensitive both to emission naturally emitted by threat materials, as further described, for example, in copending U.S. patent application Ser. No. 10/156,989, filed May 29, 2002, entitled "Detectors for X-Rays and Neutrons," which is incorporated herein by reference. In accordance with various embodiments of the present invention, a detector is employed of the type having high efficiency for detecting thermal and epi-thermal (intermediate energy, typically $1-10^4$ eV) neutrons. The detector uses the scintillator Gd_2O_2S , commonly known, and referred to herein, as "gadax," to stop both neutrons and the photons. X-ray-induced scintillations from the gadax in the visible portion of the spectrum are then detected, typically by photomultipliers or photodiodes. Alternative scintillators, such as LiF, for example, with high cross sections for detecting thermal and epithermal neutrons are also within the scope of the present invention.

Separate, large-area detectors are deployed adjacent to the beam plane on the x-ray source side of the scanned object, and with their active surfaces oriented toward the scanned object. These detectors need only provide a large solid angle for collection of scattered radiation; no critical alignments are required. In this location these detectors respond to x-rays which are scattered generally back toward the source from the object.

FIG. **3** shows a schematic top view of another embodiment of the invention that may advantageously be employed for the inspection of objects disposed to either side of the inspecting conveyance.

In accordance with the present invention, various inspection modalities currently in use for detection of contraband materials may additionally be used for finding fissionable material in the containers they examine. Some methods are passive; i.e., the emission of neutrons or gamma rays from radioactive materials may be signatures for an alert. Several methods for carrying out such passive measurements are described in copending U.S. Provisional Application Ser. No. 60/396,034, filed Jul. 15, 2002, and incorporated herein by reference. Other methods are active; i.e., penetrating radiation irradiates a container thereby exciting fluorescence of the fissile material and the characteristic x-rays of uranium or plutonium produce an alert signal.

Inspection of object **712** may be conducted by an operator disposed within conveyance **710**, or, alternatively, by a remotely disposed operator. For inspection, object **712** may be maintained in a stationary condition, with conveyance **710** traversing the object along direction **720** (forwards or backwards), alternatively, inspection may be conducted while both conveyance **710** and inspected object **712** are in motion. In yet another mode, referred to as a "portal mode," the system is stationary and the object of inspection is conveyed past the system. Where the object of inspection is a person, the person may be required to walk past the conveyance slowly, preferably in both directions, so that both sides of the person can be subjected to search.

Referring further to FIG. **3**, the x-ray beams in x-ray inspection systems typically sweep, as by rotation of chopper wheel **734**, through the inspection volume during a large fraction of the operating time. During the remaining fraction of each sweep cycle there are essentially no source x-rays striking the target container. Thus, during the time of source quiescence, the detectors are only counting background.

In a preferred embodiment, particularly useful for lower energy (140 keV-160 keV) x-ray systems, the output from backscatter detectors **100** are switched to a pulse counting circuit during the fraction of the operating cycle during which the source of x-ray irradiation is off. During this period,

individual neutrons or gamma rays can be detected and analyzed. The efficiency of the backscatter detectors of an x-ray inspection system for detecting neutrons or gamma ray has been discussed above.

Referring only to gamma ray detection for purposes of illustration, the 186 keV gamma rays are emitted in 53% of the decays of ^{235}U but only a thin layer of the bulk uranium is accessible since the mean free path of 186 keV gammas in uranium is only 0.36 mm. Still, every square centimeter of 10% enriched uranium will emit ~two thousand 186 keV gamma photons per second, giving rise to a count of $2,000 \times 0.004 = 8$ counts for every square centimeter of surface area of uranium that faces the detectors. A 1" cube of uranium (weighing $\sim 3/4$ pounds) would signal its presence with ~ 50 counts in the 0.2 second off-period of the inspection. A signal of this magnitude is easily discriminated. The signal strength is further increased by increasing detection efficiency, enlarging the detectors, and increasing the off-time of the sweeping x-ray beam.

In a "stationary mode," both the system and the object being scanned are stationary, and a vehicle-mounted x-ray scanning method, configured as a part of the system itself, is employed to create in effect both horizontal and vertical scanning to generate a backscatter x-ray image. Such methods may include the use of an x-y translation stage, electronically-steered x-ray sources (as described, for example, in U.S. Pat. No. 6,421,420, or other means.

In other embodiments of the invention, now described with reference to FIG. 4, a source of penetrating radiation, including x-ray tube 732 and chopper 734, as well as scatter detector modules 100 are included within a static imaging module 800, shown with its top panel removed for convenience of depiction. In practice, it is advantageous that all components of the x-ray inspection system be concealed within imaging module 800, so as not to be discernable from outside the module. Imaging module 800 is advantageously a standard shipping container (such as a TRICON triple container, standardized for ground and air transport), and may contain attachment points for helicopter deployment to a location where it remains static for some duration.

The x-ray beam is swept in a vertical swath, depicted schematically by the partial plane designated by numeral 802. An inspected object 804, exemplified here by a vehicle, is scanned by x-rays as it traverses plane 802. X-rays scattered by object 804 are detected by detector modules 100, which x-rays transmitted, or forward-scattered, through object 804 and detected by transmission or forward-scatter detectors (not shown) disposed within a forward-detection housing 806.

In accordance with preferred embodiments, imaging module 800 is deployed operationally in conjunction with one or more other containers, as shown in FIG. 5, such as power module 500 and operator module 502, containing an operator console 504, all intercoupled by power and telemetry connections for coupled operation.

FIG. 6 shows a side view of an embodiment of the invention, in which detector modules are operationally deployed outside, rather than within, an enclosure 600, where, in this embodiment, the enclosure is a trailer that may be drawn to the site of operation behind a vehicle. FIG. 7 shows a rear view of the embodiment of FIG. 6.

Forward Scatter Detection in Backscatter Inspection Scenarios

Detection, using illumination by penetrating radiation, either from a mobile platform such as the Mobile Inspection Van described in U.S. Pat. No. 7,099,434, or from a fixed platform such as the Ruggedized Detection Imaging Mod-

ule™ (RDIM), may be enhanced with respect to the detection of metal objects, such as might be concealed, for example, within a metal container. Embodiments of the present invention offer improved detection of a metal object within a metal container by adding a stationary transmission detector on the other side of the object being scanned with a pencil beam, where the source of the pencil beam, and either backscatter, forward scatter, or transmission detectors are concealed from view from the vantage of the inspected object.

Thick metallic materials disposed can be clearly seen in the transmission image, derived as shown in FIG. 8, where attenuated, or blocked, transmission is due to the high attenuation of x-rays in these materials. As used herein, the term "metallic" is a proxy for materials of high "Z", where Z represents the atomic number characteristic of the material. For example, artillery shells will appear as very dark objects in the transmission image, with little or no x-rays penetrating through them. Note that this can be done when the Mobile Inspection Van 400 is operated either in motion or in the stationary portal mode. FIG. 8 depicts source 402 and backscatter detector module 404 disposed within Mobile Inspection Van 400, and x-ray beam 406 scanning object 408. Transmission detection module 410 is here comprised of an upright vertical segment 412 and a horizontal segment 414.

One way to help mitigate the problem of imaging organic materials within or behind significant amounts of high-Z material (such as metal) is to add some forward-scatter detectors 500 as shown in FIG. 9. Because the forward-scattered x-rays 510 detected in these detectors have only been scattered through small angles (typically in the range of scattering angles, $5^\circ < \theta < 30^\circ$), the average energy of the forward-scattered x-rays is significantly higher than the energies of back-scattered x-rays (which are typically no greater than about 90 keV for a primary x-ray beam from a 225 kV x-ray source). This is due to conservation of momentum in the Compton scattering process. The higher energy of forward-scattered x-rays allows them to more easily penetrate the steel in the vehicle body and be detected. The signal from the forward-scatter detectors can either be combined with the backscatter signal, or it can be displayed separately to the operator.

A method for integrating the horizontal section of the transmission detector 414 and the forward scatter detectors 500 into a rapidly deployable module is shown in FIG. 10. The detectors have been integrated into a re-locatable "speed bump" 600 which can be conveniently stored inside the back of the Mobile Inspection Van and which is placed on the roadway prior to commencing scanning vehicles. If necessary, the speed bump can be conveniently broken down into three smaller modules for storage and ease of handling. The vertical leg of the transmission detector would be a separate unit set up on the far side of the vehicle being scanned. X-ray beam axis 602 is shown.

It should be noted that all the claims made in this disclosure are applicable not only to the Mobile Inspection Van as in the earlier referenced patent application, but also to any application of radiation backscatter technology, such as in a ruggedized shipping container that contains similar subsystems as a Mobile Inspection Van.

Returning now to embodiments of the invention in which the relative motion of conveyance 710 and object 712 (shown in FIG. 1) may be carefully controlled or may be monitored by sensor 718 which employs any of a variety of sensing methods, such as radar, ultrasound, or optical, including laser or LIDAR sensing, all provided as examples only, in order to sense the relative speed of conveyance 710 with respect to object 712. A signal provided by sensor 718 is employed by controller 740 in one or more of the following modalities:

The vehicle speed may be regulated, or, alternatively, the pixel registration may be corrected to compensate for vehicle speed anomalies so as to produce aspect-ratio-correct, distortion-free, backscatter x-ray images. Relevant techniques include but are not limited to:

Use of high precision speed-sensing devices to accurately measure vehicle speed at low (0.5 to 10 mile-per-hour) ranges;

low-speed (0.5 to 10 mile-per-hour) electronic and/or software-based engine and/or transmission controls;

custom vehicle drive-train gear design, which simultaneously produces low vehicle scan speed while maintaining the capability of offering roadworthy speed ranges, up to at least 55 miles per hour. In this context, the cruise-control system of a vehicle may be 'co-opted' to govern motion at low scanning speeds.

over/under-speed indications to the driver, using high-precision sensing devices coupled to a dashboard indicator, which the driver uses to manually adjust throttle and braking to maintain the desired vehicle speed within the range necessary to maintain distortion-free images;

friction drive for driving the wheels of the inspecting vehicle during inspection operations;

dynamic on-the-fly software correction. This method does not attempt to regulate vehicle speed but rather uses real-time high-precision vehicle speed and speed variation data from on-vehicle sensor(s), of which a tire-driven embodiment is designated by numeral **26**, together with software algorithms which interpolate, average or in other ways correct for the aspect ratio distortion in the x-ray image data produced by off-speed or varying speed.

Remote sensing of the object's speed using one or more of a variety of sensors **718** and using signals generated by sensor **718** in software algorithms together with the vehicle speed data to effect dynamic aspect ratio correction of the backscatter x-ray image.

The foregoing methods for control and correction of relative motion variations may be used either singly or in combination, within the scope of the present invention. Sensors **718** may additionally provide for control of x-ray beam direction such that the relative speed and track angle of the source with respect to the scanned object may be actively tracked. This capability may advantageously allow improved images to be formed at faster speeds and, additionally, allow for relative motion that is not purely unidirectional. It should be noted, additionally, that in circumstances where no horizontal spatial resolution is required, detection of relative motion is obviated.

FIG. **2** depicts a row of five vehicles scanned by a system as described in the present application, showing concealed contents of the vehicles in the various cases.

In the drive-by case, dosage to stationary people is readily reduced below regulatory thresholds provided vehicle speed is maintained above a specified minimum while x-rays are on. An interlock is provided to cut off x-ray generation when vehicle motion ceases or falls below a specified minimum speed. Otherwise, x-rays may be enabled regardless of proximity to objects.

For the stationary case, or for drive-by cases where additional safety measures are required or desired, proximity sensors, such as laser, microwave, ultrasound, or thermal sensors, for example, may be employed to determine the presence of objects to be scanned, enabling x-rays only when necessary, and/or to discern if humans are in the beam path. These sensors typically operate all the time, with their signals processed via software and/or hardware to intelligently control

x-ray generation. The operator may also be provided with a manual "x-ray enable/deadman" control, in addition to any other safety devices and controls.

Features of the present invention may advantageously be employed in applications including, but not limited to, the following:

Inspection/manifest verification of containerized, palletized, or other packaged cargo, trucks or trailers being transported across or staged at ports, borders, air terminals, or similar transportation sites.

Verification that containers, objects, or vehicles are empty as claimed.

Inspection of vehicles attempting to enter controlled or high-value areas such as military bases, power plants, tunnels, air terminals, public or government buildings, parking garages, lobbies, service or delivery areas, toll-booths, or other important installations, for contraband or threats such as explosives, weapons, or smuggled personnel.

Inspection of vehicles or containers parked in garages, lots, or on public or private thoroughfares for explosives, weapons, contraband, or other threats.

Inspection of vehicles in motion for threats, contraband, or to verify contents.

Inspection of objects potentially containing radioactive materials that produce neutrons and or gamma rays.

Searching surrendering soldiers/civilians to ensure they are not wired.

Searching personnel at border crossings/checkpoints to screen out suicide bombers.

Scrutinizing persons in large groups.

Distant Detection of Backscatter

Embodiments of the present invention (which may be referred to as "Z-Radar"TM) are now described with reference to FIG. **11**. A backscatter inspection system, designated generally by numeral **900**, use a collimated beam **102** of penetrating radiation, such as x-rays, to illuminate an object **104** (which, as indicated above, may include a person) at relatively large distances, to determine, for example, the metallic content on or within the object. An object will be said to be disposed at a "large distance" if the object of inspection, or a relevant portion thereof, subtends an angle of less than 5° in any direction as viewed from the source of illumination. Penetrating radiation may also include, for example, waves in other portions of the electromagnetic spectrum, such as gamma rays, but will be referred to, herein, as x-rays, without intended loss of generality. When the penetrating radiation is comprised of x-rays, the x-rays may be generated by an x-ray source such as x-ray tube **110**.

Penetrating radiation **106** scattered by the inspected object is detected in large-area x-ray detectors **108**, and the signal generated by detectors **108** is compared, by controller **112**, with the expected signal from organic objects illuminated with x-rays at that distance. Objects containing metals absorb the x-rays, resulting in a backscatter signal which is lower than the signal expected from a purely organic object.

Inspected objects can include without limitation people or any object which consists mostly of organic material, on or within which a determination of the metallic content is desired. For example, the metallic shrapnel used by a suicide bomber to maximize the lethality of the explosive being carried may be detected, or the presence of metallic weapons, such as guns and knives may be detected.

In some embodiments, the object to be examined is initially located and tracked with a system utilizing one or more video cameras **114**, although any other optical or non-optical means may also be employed, within the scope of the invention. FIG.

11 shows various functional components according to one specific embodiment of the present invention. Video cameras 114 of an optical surveillance system monitor an area of interest. A steerable x-ray source 110 is mounted on a base 116 which can rotate and translate the position of a penetrating x-ray beam generated by x-ray tube 110. Backscatter detectors 108 detect the backscattered x-rays 106 from the target object 104 being illuminated. The video tracking system may be used to point the x-ray beam onto the object of interest. A shutter (not shown) can then be opened to allow the x-rays to briefly illuminate the target object for a pre-determined time period (known as the interrogation time). A data acquisition system records the intensity of a signal received from the backscatter detectors.

Referring now to FIGS. 12A and 12B, in order to accurately calibrate the backscatter signal intensity, several illumination points (or "interrogation" points) 202, 204 can be chosen on the target 200, or on similar targets at the same distance. If the signal from one or more interrogation points appears significantly lower than that from the other interrogation points, it can be used to indicate the presence of metallic materials. On that basis, in accordance with embodiments of the invention, a descriptive category is determined, such as that of a heightened security threat according to pre-established security threat criteria, and appropriate action can then be taken accordingly.

Embodiments may also be suitable for determining the presence of organic materials on or within objects which largely consist of metallic materials. An example of this could be looking for explosives concealed in the door of a vehicle. For this application, interrogation points with a higher than expected signal are indicative of the presence of concealed organic material.

For objects which are relatively close to the x-ray source, the backscatter signal can also be used to detect the presence of dense organic material (such as explosives) concealed on an organic target object with a lower density. These materials tend to backscatter x-rays somewhat more strongly than less dense organic materials, such as the human body.

In Table 1, the results of a computer simulation are shown for an x-ray backscatter interrogation system operating at three source voltages of 160 kV, 450 kV, and 1.2 MeV. The simulations involved looking at the backscatter signal from a person at various distances, and comparing the signal with the signal from a person carrying a steel sheet or a person carrying PETN explosive containing ball-bearings as shrapnel. The signal to noise ratio (SNR) is defined by:

$$SNR = \frac{N_{Person} - N_{Person+Steel}}{\sqrt{N_{Person}}}$$

where N_{Person} is the number of detected backscattered x-rays from a person carrying no steel and $N_{Person+Steel}$ is the number of detected backscattered x-rays from a person carrying steel. It can be seen that the performance of the 225 kV and 450 kV systems is essentially the same, but considerably better than the performance of the 1.2 MV system. Since a 160 kV system would be much cheaper and more compact than a 450 kV system, a preferred source voltage is about 160 kV. The following Table indicates the results of a computer simulation showing the signal-to-noise ratio for detecting metal on a person (in the form of a steel sheet or a matrix of 0.25" ball-bearings) with an x-ray backscatter interrogation system operating at three different source voltages and various stand-off distances.

| Source Voltage | Standoff Distance (feet) | SNR (Steel) | SNR (Ball Bearings) |
|----------------|--------------------------|-------------|---------------------|
| 160 kV | 50 | 77.2 | 47.5 |
| | 100 | 11.5 | 9.8 |
| | 150 | 3.3 | 2.7 |
| 450 kV | 100 | 11.1 | 9.9 |
| 1.2 MV | 100 | 4.4 | 4.5 |

10 Calibration of the Backscatter Signal

As discussed above, some embodiments employ techniques for calibrating the strength of the detected backscatter signal with a reference signal in order to determine whether the signal from an interrogation point is low enough to signify the presence of metal. This can be done in a number of ways:

1. Determine the distance to the target object being interrogated (for example, by using information from the video system or using a laser range finder) and use lookup tables to determine the maximum backscatter signal for metallic material. One disadvantage of this approach is that the system hardware should be relatively stable.
2. Compare the signal strength from a number of interrogation points from objects all at approximately the same distance.
3. Compare the signal strength from a number of interrogation points 202, 204 from different locations on the same object. This approach is shown schematically in the FIG. 12A.
4. Acquire a line scan 210 (shown in FIG. 12B) consisting of many interrogation points across the object, and look for regions 208 on the object where the backscatter brightness is significantly lower than for the rest of the object 206. This approach is shown schematically in FIG. 10B.

One method for simultaneously acquiring interrogation data and obtaining a reference signal is illustrated in FIG. 13. In this embodiment, the collimation scheme, such as multiple collimators 302 allows for several highly-collimated x-ray beams 304 to be produced simultaneously. A rotating shutter 306, disposed within x-ray cone beam 308 produced by x-ray source 300, is then used to ensure that at any instant only one of the beams is actually illuminating the target object 104. For the example shown in FIG. 13, this means that four interrogation points can be acquired in the time that it takes the shutter to rotate through one revolution. One advantage of this embodiment is that the speed of operation of the system can be enhanced, as the beam collimators do not physically have to be re-directed between interrogation points. The system may only have to be targeted once onto the central region of a suspicious object. The number of beams and their orientation with respect to each other can be optimized for the particular target objects being inspected.

One specific embodiment of the present invention operates as follows:

1. An operator identifies a suspicious target which he wishes to interrogate with the system. This could be done, for example, by clicking a mouse on the suspicious object in a video image. The operator may wish to identify, for example, a person wearing bulky clothing or carrying a backpack.
2. The interrogation system then sends out a pulse of x-rays in a highly-collimated beam, directed at the target object. By comparing the return backscatter signal with a reference signal (using one of the calibration methods discussed above), the system automatically determines the threat level of the object.

15

3. The system then alerts the operator, who can then determine what further action needs to be taken. If the threat determination is deemed to be uncertain, the system could continue to track the suspicious target using a video tracking system, and could perform a further confirming interrogation (if required) at a closer distance.
4. For confirmed threats (targets with substantial metallic content), the system may then initiate further inspection using additional systems that employ other inspection or detection modalities, such as x-ray backscatter imaging, mm-wave imaging, or terra-Hertz spectroscopy. These may be used to confirm the presence of weapons or explosives on or within the target object.

Bi-Static Compton Scatter Imaging

Equipment and methods are presented here to extend the useful range of Compton scatter imaging systems by separating the location of the x-ray detectors from the x-ray source. In each application the detectors are closer to the subject than the rest of the imaging system, allowing for more scattered flux to be collected than if the detectors were co-located with the x-ray source and other equipment. The arrangement of source, target, and detector is analogous to many applications of bi-static radar.

Because a number of factors figure in the ability to form images from a distance, extending the useful range of a backscatter imaging system may provide one or more of the following advantages: better image quality for a given distance, larger field of view for a given image quality at a given distance, shorter scan time to produce a given image quality at a given distance, and reduced dose to target for a given image quality at a given distance. Long range imaging systems have a variety of security applications. Reduced dose imaging systems are particularly important for the inspection of people.

An inspection system in accordance with preferred embodiments of the present invention is now described with reference to FIG. 14. A source 12 of penetrating radiation directs a beam 20 of penetrating radiation at object 16. Source 12 of penetrating radiation is disposed, with respect to object 16, such that the inspected field of view is less than 0.1 steradians (sr). Object 16 scatters flux 22 which is detected by detector 14. Detector 14 is disposed, with respect to the object, such as to subtend greater than 0.5 steradians in the field of view of the object.

Application to Inspection of Walls for Foreign Objects

In one embodiment of the present invention, now described with reference to FIG. 15, the inspection system is configured to rapidly inspect walls for unwanted objects, or perform a variety of non-destructive testing applications such as looking for flaws hidden under the body panels of automobiles.

FIG. 15 shows a configuration where source 12 is moved to the center of room 26, from which source 12 can rapidly scan walls 24 of room 26 with penetrating radiation. Detectors 14 are placed near to walls 24. In this configuration, the system can image all of the sections of walls 24 that are not covered by detectors 14. The positions of detectors 14 can then be shifted to allow the inspection system to scan the remaining areas. If source 12 is not displaced when detectors 14 are moved, then both images can be stitched together in software to provide a modest quality image of room 26.

Regions that are found interesting can be scanned more closely using traditional methods whereby both source 12 and detector 14 are placed as close as possible to the area under inspection.

16

Application to Locate People in Rooms from Adjacent Rooms

In another embodiment of the present invention, shown in FIG. 16, source 12 is located in an adjacent room 28 and detectors 14 may either be built into walls 24, as shown in FIG. 16, or located in adjacent rooms 28, as shown in FIG. 17. Concealment of detectors may be advantageous in particular applications. Wireless transmitters 30 can be used to connect detectors 14 to a data processing apparatus 32 co-located with X-ray source 12.

In such a configuration, operators are able to first produce a low-dose/low-quality scan that might provide enough information to separate perpetrators from victims. Then, if needed, higher quality higher-dose images could be produced of the perpetrators. In this way, high dose could be limited to a hostage taker while minimizing dose to innocent hostages.

Application to Extend Range of Existing Inspection Systems

As shown in FIG. 18, AS&E presently builds a backscatter imaging product known as the Z-Backscatter Van™ (ZBV™), described, for example, in U.S. Pat. No. 7,099,434. The ZBV, designated generally by numeral 90, is optimized for a target distance of 2-5 feet. ZBV 90 is often deployed in “portal mode”, meaning that the ZBV, with X-ray source 12 and detectors 15, is stationary, while target 13 (typically vehicles) drive through the scanning x-ray beam 20.

In the portal operating mode, the range of the ZBV 90 is extended by deploying additional detectors 14 nearer to target 13, as shown in FIG. 18. Such a configuration may have the following advantages over reliance on ZBV’s on-board backscatter detector array 15:

In the event of a detonation of the target, only auxiliary detectors 14 would be destroyed.

An arbitrary number of detectors 14 could be deployed, allowing users in the field to trade cost for added image quality when and where needed.

Positions of detectors 14 can be rearranged by the user to vary shadowing; to emphasize data from side scatter or forward scatter; or even to produce transmission x-ray images.

Detectors 14 can transmit data to ZBV 90 electronics by using wireless transmitters 50. The only power needed by detectors 14 is direct current provided by power supplies for the photomultiplier tubes, which may be powered by batteries, and power for the wireless transmitters 50. Alternately, power and signal cables may be used to connect ZBV 90 to detectors 14.

Detectors 14 are one of the lighter components of the overall x-ray system. A small number of auxiliary detectors can fit into the coach of ZBV 90. A larger supply of detectors can be towed in a small trailer (not shown) behind ZBV 90, or transported in other support vehicles (not shown). As shown in FIG. 19, in order to operate ZBV 90 in drive-by mode (where ZBV 90 drives past target 13 in order to scan X-ray beam 20 over target 13), auxiliary detectors 14 are mounted on robotic drone vehicles 42. In this scenario a wireless link is used to transmit instructions to robotic drone vehicles 42, and to receive data from detectors 14.

Application Using Forward Deployed Mobile Detectors to Inspect Possible IEDs or Left-Behind Packages

An inspection system for detecting possible improvised explosive devices (IEDs), in accordance with the present invention, is now described with reference to FIG. 20. Detector 14 is mounted on small robotic drone vehicle 42. Small robotic drone vehicle 42 brings detector 14 close to IED 40 while x-ray source 12 remains at a safe distance with the operator (not shown). Although robotic drone vehicle 42 is a relatively high cost component compared to a backscatter x-ray system, small robotic drone vehicles 42 designed for

military applications have often survived explosions, and robotic drone vehicle **42** could be further protected with blast armor.

The location of detector **14** with respect to IED **40** causes different shadowing effects in the resulting image. If detector **14** is placed on only one side of primary x-ray beam **44**, the image will have shadows analogous to what one would see in a photograph with the camera at the position of x-ray source **12** and with a light source at the location of x-ray detector **14**. These shadows often prove useful in interpreting images, as they give objects a three dimensional appearance and make certain edges more apparent. More edges can be enhanced by moving detector **14** to a new location, or using several detectors simultaneously with data from each detector **14** processed separately. Experiments at AS&E have shown that the effect can be even more useful when images from several detectors at two or more angles are mixed in different ratios.

Two or more detectors **14** on two or more robots **42** can be used to fully exploit this detector mixing concept. Alternately, after a single image is produced using a single detector **14**, detector **14** can be moved to a new location while x-ray source **12** does not move, and then a second image is produced. These sequential images could be combined (to increase the effective flux) and mixed in different ratios to exploit different possible shadow configurations.

Application Using Forward Deployed Mobile Detectors to Scan a Roadside for IEDs

A fully mobile variant of the previous embodiment is capable of 'sweeping' for roadside IEDs, as shown in FIG. **21**. X-ray source **12** is mounted on vehicle **46**. Vehicle **46** may or may not be armored. A beam chopper wheel (not shown) scans beam **20** in a direction perpendicular to road **48** while vehicle **46** drives slowly in the direction of road **48**, in order to produce a 2-D image. Detector **14** would drive ahead of vehicle **46** on a small robotic drone vehicle **42**. If cable management between the vehicle **46** and robotic drone vehicle **42** poses a problem, then cabling can be replaced by wireless communication system **50** to direct robotic drone vehicle **42** and receive signals from detector **14**.

As depicted in FIG. **22**, x-ray source **12** may be attached to swivel mount **52**, so that either side of road **48** can be imaged, or object **40** lying in road **48** can be inspected.

Variations in the speed of vehicle **46** can cause distortions in the image. These variations typically do not inhibit the interpretations of backscatter images, however, the distortions might be more problematic in long-range applications. A scan drive might be employed to regulate the speed of both vehicle **46** carrying x-ray source **12**, and robotic drone vehicle **42** carrying detector **14**.

A greater challenge is posed by uneven road surfaces and bumps in the road. These cause x-ray source **12** to bounce up and down, producing corresponding distortions in the image. Although these distortions are usually not a problem for scans at a distance of a few feet, their effect will grow in proportion to the distance. A change in the attitude of the vehicle of one degree, for example, will move beam **20** only 1" at a distance of 5 feet. However, beam **20** will be displaced by 6" at a distance of 30 feet. A given distortion will be even more apparent (relative to existing systems) because long range systems such as the present invention will typically work with much smaller fields of view than have been used on short range systems.

In accordance with various embodiments of the invention, x-ray source **12** is stabilized using the same technologies that are used to stabilize the cannon on a modern tank. Since the chopper wheel (not shown) itself is large gyroscope, the chopper wheel may be mounted on a suspension of gimbals and

shock absorbers to minimize changes in attitude of x-ray beam **20** while vehicle **46** moves over uneven terrain.

The image is much less sensitive to changes in the position of detector **14**. Changes in attitude or elevation of detector **14** during a scan would cause only small changes in the shadowing of the image, which would not interfere with interpretation of the image, and would likely not even be noticed.

Application for Surveillance of Select Vehicles or Persons Traversing a Defined Passageway

In another embodiment of the bi-static backscatter concept, persons or vehicles subject to inspection might be directed to traverse a well defined region. This region might be a walkway in an airport or a roadway or tunnel through which vehicles pass.

Existing concepts for inspecting every person in such a situation require space for a complete backscatter source and detector adjacent to the through-way. Moreover, subjects must pass through the beam at a specified speed, subjects are only inspected from the side, and every subject passing through the inspection area must be irradiated.

Situations where any one of the above constraints is unacceptable can be addressed by a configuration such as is shown in FIGS. **23** and **24**. X-ray sources **12** are attached to pivoting mount **54** aimed to select any arbitrary subset of a larger region for scanning with x-ray beam **20**.

In each of these systems, operators select person **56** (in FIG. **23**), or vehicle **58** (in FIG. **24**), and paint only that target with X-rays. Person **56**, or vehicle **58**, can be studied for as long as it is within passageway **60** which is lined with detectors **14**.

If passageway **60** is a narrow hallway, (or if the roadway passes through a tunnel) then detectors **14** can easily be concealed in walls and/or ceiling or disguised as part of the walls or ceiling. In some circumstances it might also be feasible to build detectors **14** into the surface of passageway **60**. In a configuration where detectors **14** are deployed in the walls, floor, and ceiling of a tunnel, it is possible to achieve coverage of nearly 4π sr, thereby making use of the greatest possible fraction of scattered photons. Such a system achieves far higher collection efficiency of scattered photons than current near-field, Compton scatter imaging systems.

As shown in FIG. **23**, x-ray sources **12** may be located in the ceiling so operators are better able to steer around uninteresting people. In FIG. **25**, x-ray sources **12** are drawn at the side of passageway **60**. However, in a tunnel, X-ray sources **12** may also be suspended from the ceiling.

The use of multiple X-ray sources **12**, or even a single x-ray source **12** which can be aimed from the middle towards both ends of passageway **60**, allows operators to image person **56** or vehicle **58** from multiple angles. If multiple X-ray sources **12** are aimed at the same object, or objects that are near to one another, then the X-ray sources **12** need to be electronically synchronized so that at any instant, only one is shooting.

Encoders on the source-aiming mechanics may be used to identify target location(s) and only allow signal from nearest detectors to be processed, in order to limit electronic noise and air scatter.

By imaging person **56** or vehicle **58** from a distance, speed becomes a less critical factor than in near field imaging systems, because angular speed is much smaller when viewed from a distance. Imaging the target from an angle that is nearly in line with the target's direction of motion further reduces apparent angular movement and further facilitates the imaging of a moving object.

Detectors **14** built into the floor or road surface, as shown in FIGS. **25** and **26**, must be able to support the weight of any object **80** (people, animals, or vehicles) that might move over

them. Strong solid supports such as steel plates are typically not used on the fronts of Compton scatter detectors because the energy of the Compton scattered x-rays is typically too low to penetrate such structures. However, structural support grid **62** made of a structural material (such as steel) can be placed over detector **14**, as is shown FIGS. **25** and **26**. The detection efficiency of detector **14** will only be reduced by that fraction of detector area which is blocked by solid parts of structural support grid **62**. The structural support grid **62** will not produce artifacts of any kind in Compton scatter images, because Compton scatter x-ray images are spatially modulated by the movement of the primary x-ray beam, rather than by pixilation of the detectors **14**, as is the case in most transmission x-ray and optical imaging systems.

Detector **14** may be concealed, by camouflage **64**, or otherwise, in some cases, at the further expense of attenuating the x-ray signal. In outdoor applications, a thin layer of dirt or leaves might be used. In an airport walkway a thin sheet of plastic with decorative patterns could obscure any identifying features of detector **14**.

Application for Broad Area Surveillance

In another embodiment, shown in FIGS. **27** and **28**, an array of detectors **14** is located in regions of interest, and the entire region may be "painted" by single x-ray source **12**.

Detectors **14** are arrayed in or on the ground in the region for surveillance. X-ray source **12** is in a central location, able to "shoot" at all regions where detectors **14** are located. This way X-ray flux used for imaging each pixel of a given target is roughly independent of distance, because no matter where in the region object **82** stands, object **82** is still roughly the same distance from the nearest detectors **14**. X-ray source **12** might scan azimuthally through as much as 360 degrees, in a manner similar to a radar system.

In this continuous sweep mode, once the scan area is surveyed, the backscatter signal at any point should not change unless a new object were introduced. Therefore, a computer could monitor the image, or just the integrated signal from any given region in the image, and alert human operators in the event of a change. A sudden increase in image density might indicate the presence of a living intruder (person or animal). More subtle changes might indicate motion of objects (e.g. vehicles entering the region, or movement of camouflaged people/vehicles that have been hiding in the region since before the scan started). Alternately, an optical or infrared imaging system might be used in a similar way to automatically detect potential threats. Once a potential threat is flagged, the system could automatically begin a more detailed Compton x-ray scan to produce an image to be analyzed by a human operator.

Pressure sensors (not shown) might be integrated with detectors **14** in the ground. In this case, the pressure sensors would be the first detection system. Then a computer might automatically aim the X-ray beam **20** at the region in question and produce an image.

A continuous sweep mode may also be used to scan a crowd for potential suicide bombers.

Pressure sensors integrated with detectors **14** and placed in the ground around detectors **14** may be used to sense when object **82** is moving in parallel with the path of the beam. This information can be used by an automatic safety system to limit the dose to object **82** by shutting off beam **20** or changing the sweep path. The best solid angle coverage is achieved with a tiled pattern of detectors **14** 'carpeting' the ground.

In certain embodiments of the invention, detectors **14** may be camouflaged by thin layer of dirt, or otherwise concealed, although some forms of camouflage may result in a reduction in signal. Alternatively, or additionally, detectors **14** may also

be hidden in above-ground objects such as artificial rocks or trees, although a large solid angle coverage would be unlikely in this case.

Detectors **14** may be deployed as free standing monoliths **68**, as shown in FIG. **29**, though a large solid angle would require filling much of the area with monoliths **68**, which might obstruct visual lines of sight from x-ray source **12** to potential targets of interest. Building **70** and other sensitive structures might have detectors **14** mounted on the building walls.

Electronic noise could be limited by only processing signals from those detectors **14** that are near the target of the x-ray beam **20**.

If the beam **20** is fired directly towards a detector **14**, that signal is processed separately, as it would be predominantly a transmission image signal rather than a Compton scatter signal. Encoders on the source positioning device could indicate the position of the x-ray beam spot in order to indicate to the control system when detector **14** is in the direct path of beam **20**.

The electronics and software are designed to allow the user to deploy and configure any number of detectors **14** in any chosen configuration. Different terrain and different applications would require different configurations and numbers of detectors **14**.

Air scatter becomes a more important consideration when scanning at a distance. Detectors **14** near to the primary beam **20** receive an air scatter signal which will 'fog' the image. The noise caused by this effect might be mitigated by reading the signals from detectors **14** at different distances in separate channels **74**, as is shown in FIG. **30**, so that person **76** is imaged in only one detector, and that image contains only the air scatter background from that detector (or the set of detectors in that region). Detectors **14** located along the path of the primary beam **20** which are not near to the target receive much less signal from the target and therefore have a much higher ratio of noise to signal. The overall signal-to-noise ratio would be improved by ignoring the entire signal from these detectors.

Although various exemplary embodiments of the invention have been disclosed, it should be apparent to those skilled in the art that various changes and modifications can be made which will achieve some of the advantages of the invention without departing from the true scope of the invention.

What is claimed is:

1. A method for inspecting a target object comprising:
 - a. generating a beam of penetrating radiation with a source of penetrating radiation;
 - b. collimating the beam of penetrating radiation with a collimator to form a collimated beam;
 - c. scanning the collimated beam across the target object;
 - d. detecting radiation backscattered from the collimated beam by a plurality of interrogation points across the target object;
 - e. deriving expected reference values based on reference to scanned portions of the target object;
 - f. comparing characteristic values of the backscattered radiation to the expected reference values; and
 - g. determining a descriptive category based on the comparing of which descriptive category characterizes the target object.
2. A method according to claim 1, wherein the penetrating radiation is x-ray radiation.

21

3. A method according to claim 1, wherein the descriptive category indicates abnormally high metallic content when the characteristic values are less than the expected reference values.

4. A method according to claim 1, wherein the descriptive category indicates abnormally high organic content when the characteristic values are greater than the expected reference values.

5. A method according to claim 1, wherein the descriptive category indicates a potential security threat according to pre-established security threat criteria.

6. A method according to claim 1, wherein the descriptive category indicates a confirmed security threat according to pre-established security threat criteria.

22

7. A method according to claim 1, further comprising: selecting a particular target object for illumination.

8. A method according to claim 7, wherein the selecting is based on optical surveillance of an area of interest.

9. A method according to claim 7, wherein the selecting is based on non-optical surveillance of an area of interest.

10. A method according to claim 1, further comprising: determining the expected reference values based on illuminating a reference object with the penetrating radiation.
